**Abstract**—The complexity of image processing algorithms using mathematical calculations grows from the nature of the image to be processed and the desired result. A hardware implementation of these algorithms for the needs of real-time and embedded systems improves performances. In this paper we present some existing approaches used for hardware systems modeling. We propose a new graphical tool for designing image and video processing embedded systems called VIP DESIGN (Video and Image Processing Design). The novelty of our approach is that we bypass the shortcomings of existing languages by providing a high level of abstraction through two kinds of diagrams: structural diagram and filter edition diagram. It also allows formal verification and automatic code generation for ASIC and FPGA implementation.

**Keywords**—*image processing; real-time; embedded system design; formal verification;*

## I. INTRODUCTION

The growth of images resolution, the nature and diversity of associated applications require implementation of complex image processing algorithms. Sequential implementation of these algorithms has quickly shown its limitations, particularly for real-time applications, due to the important quantity of data to be processed and the strong temporal constraints that characterize such systems [1]. A hardware implementation, which allows parallelizing some parts of the processing and reducing the execution time and consumption of resources, seems to be the best solution to meet time and budget requirements.

FPGA (Field Programmable Gate Arrays) is the suited platform to achieve this goal [2]. The implementation of image processing applications on FPGAs differs significantly from the one used on platforms using conventional processors and a large space of memory. For FPGAs, we have to define the algorithm itself and the hardware architecture on which it will be implemented.

In this context, the development and implementation of image processing algorithms on FPGAs, using descriptive language, is an arduous, difficult and costly task in terms of development time, readability and maintainability.

The development of a graphical language for designing image processing algorithms would reduce development effort, improve the clarity of the solution and serve as a reliable communication tool. It will provide an opportunity to represent

graphically the solution which will be automatically translated into a low-level hardware describing language.

This paper presents a graphical language for image and video processing for embedded systems design called VIP DESIGN. We developed this tool to allow design at high level of abstraction while providing an opportunity to detail designed system behavior and automatic generation of code that can be synthesized for hardware implementation needs. The time constraints paradigms integrated in VIP DESIGN make it appropriate for modeling real-time [1] applications.

## II. RELATED WORKS

In this section, we will discuss some related works and tools and present their advantages and inconveniences.

### A. Handel-C

Handel-C [3] is a low-level programming language to design hardware component such as FPGAs. It is a C-like language with extensions to control the hardware aspects of mixed systems. It integrates features to parallelize processes and can be compiled to multiple design languages (VHDL, EDIF) and then synthesized to the target hardware platform. Handel-C allows the designer to break away from the physical structure of the system and focus on its behavior. Closed to the C language, widely used, this language is easily mastered and does not require a great effort for its handling which greatly reduces the design and development time of hardware systems. However, this gain in terms of time and simplicity is combined with losses in performance due to the automatic translation from Handel-C to VHDL or EDIF. In this case, the produced code requires a manual refinement to optimize the solution implementation on hardware.

### B. UML profiles for embedded systems designs

UML profile defines a "Domain Specific Modeling Language" without contradicting the semantics of UML by:

- adding concepts relating to a particular field,
- changing the representation of these concepts,
- defining constraints applied to the associations between these concepts,
- adding constraints on the use of certain concepts or not depending on the context and the identification of semantic variation points.

SysML [4] is a UML profile for modeling systems. It incorporates additional concepts adapted to the design of embedded and real-time systems. These concepts are sometimes inadequate to the spirit of UML and suitable to the representation of hardware systems. However, they remain inapplicable in the case of a complete automated development flow [5].

Other works have attempted to use the standard notation of UML, particularly those of the activity, composition and deployment diagram, in order to model the behavior, composition and functional block for hardware systems [5]. The model thus produced can be subject to transformation and generation rules to obtain a descriptive code. This language does not provide sufficient flexibility to define other specific concepts such as data types (pixel, raw,...).

### C. VERTIPH

VERTIPH [6] (Visual Environment for Real-Time Image Processing in Hardware) is a design environment for image processing applications for real-time systems. It offers three views covering different aspects of an image processing system: An architectural view, a computational view and a scheduling and resource sharing view. This language attempts to meet the specificity of image processing applications to be implemented on FPGAs in terms of data types, reuse of primitive functions specific to this area and the graphical representation of competitive and sequential execution of different functional blocks of the designed system. However, although it is considered as a high-level design environment which don't require hardware knowledge, this tool requires a perfect mastery of resource sharing concepts and a good ability to handle and define data types at a very low-level of abstraction. This specific knowledge makes the use of this tool inaccessible to a large developer community unaccustomed to such concepts. VERTIPH doesn't integrate verification and validation of the designed model before the implementation phase considered expensive in terms of time and cost.

## III. VIP DESIGN

In order to dispel difficulties associated with the use of textual languages and provide answers to the limits of visual languages described in the previous section, we propose a new graphical language called VIP DESIGN. This section presents our approach to develop this tool and both of its structural and filter edition diagrams.

### A. Approach

VIP DESIGN, a graphical language for image and video processing embedded systems design, proposes an approach based on a graphical representation of structural and behavioral aspects of designed system while abstracting details about the physical architecture. This is possible through two types of diagrams. Embedded and real-time image processing system has input interfaces for data acquisition and an output interface to deliver its returned results. The processing can be described as a sequence of several sequential or competitive filters which communicate through channels or shared memory.

The first diagram we use is called Structural Diagram. Its purpose is to model the structural description of the system

through a hierarchical composition of all necessary functions. A second diagram can describe each basic element of this hierarchical structure. This diagram called Filter Editing Diagram details the processing functions through a description of elementary operations and their scheduling.

### B. Structural Diagram

The definition of the metamodel of this diagram is based on the following rules:

- An image processing system consists of a set of input interfaces, a set of output interfaces, a series of filters applied to a data stream, clocks and communication channels;
- One or several filters run at a specified speed set by a clock;
- Each filter consists of an input stream of data, an output, one or more parameters and a computing entity;
- A computing entity contains instruction blocks executed in parallel or sequentially,

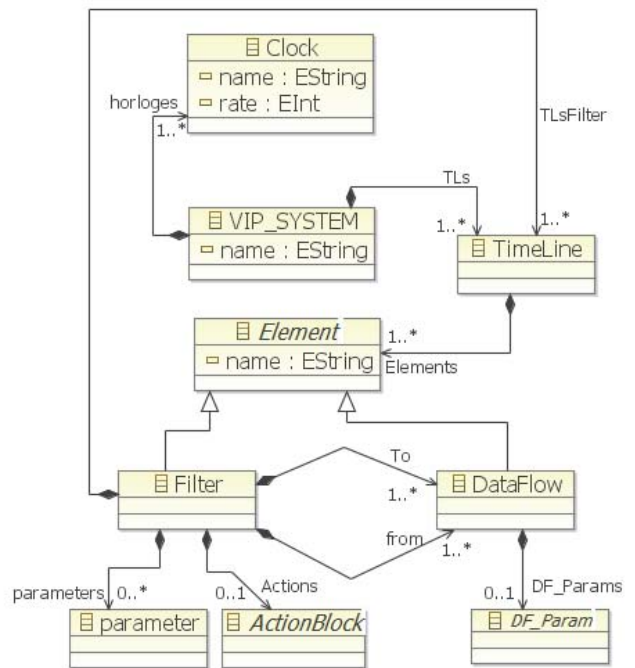

Figure 1. Partial view of VIP DESIGN metamodel

### C. Filter Diagram

The behavior of an embedded and real-time image processing system can be described by defining three basic aspects:

- An accurate expression of structural (conditional branches, loops), arithmetic and/or logic operations executed by the system;
- Scheduling of these operations;

- Defining rules to manage competitive access to shared resources;

1) *Expression of filter operation* : A clear expression of the system operations requires an action language using a concrete syntax with a sufficient level of accuracy to enable an unambiguous code generation. To meet this need, we used the package "Action" of the intermediate modeling language COCODEL [7]. It includes all the basic actions defined in [8] and [9] required to design embedded systems. This package allows to describe the body of all actions, expressions or operations of the computing entity.

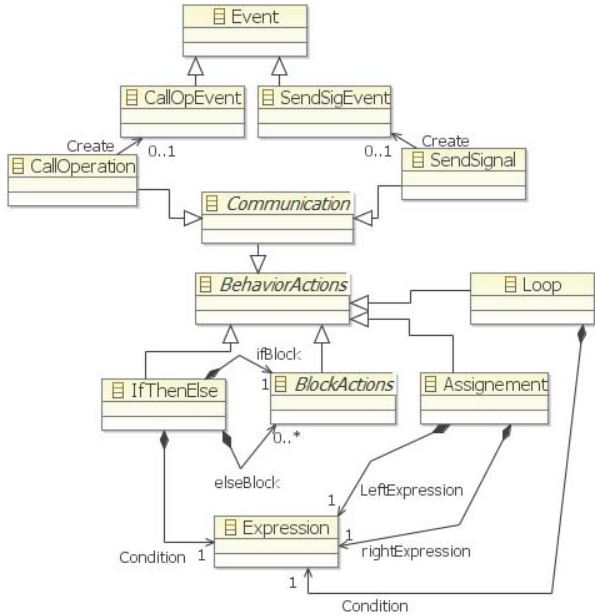

Figure 2. Package "ACTION"

2) *Scheduling* : The increasing complexity of algorithms and the large volume of data handled in image processing present a serious challenge which requires a considerable computation time to perform this complex process. Parallelizing tasks represents an effective solution to obtain more efficient in execution speed.

This parallelism can not be designed without an associated model of time. Therefore, VIP DESIGN language manages different real-time constraints related to image processing via a TIME package facilitating the addition of temporal information to model elements. This package allows to manipulate the values of temporal parameters and markup language elements with temporal information later used by tools for simulation, performance analysis, verification, validation and analysis of schedulability. In fact the components of our language are related to time through one or more clocks which gives the possibility to use multiple temporal repositories in the same VIP DESIGN model and divides time into a succession of discrete instants for modeling parallel processing, concurrency, and support the design of distributed and multi-clocks electronic systems.

#### D. Formal analysis framework

We integrated real-time constraints modeling related to image processing in the TIME package of our tool. To address these constraints, formal techniques have gained much attention since they provide fundamental techniques to analyze, validate and transform systems in a provably sound way. For that reason, we provide a verification framework to ensure the respect of time constraints at model level.

Our verification framework is based on an existing model checking, named CADP-toolbox [10]. We opted for model checking rather than theorem proving because of possibility to automatically check behavioral and timed properties. The question that we are answering is: "once we model our image processing algorithm into the FPGA, how can we check the respect of behavioral and timed requirements before going any further and generating the implementation code?"

To answer this question, we integrated a formal verification framework into our design tool. This framework takes as input both the structural and the filter diagrams, and produces as a result a formal model expressed in the form of a set of timed automata. We defined an ad-hoc domain-specified transformation language in terms of Ecore metamodel and define a Model-to-Model transformation chain. From the structural diagram, our verification framework generates a timed automaton that represents the flow of data through computing entities to check the absence of deadlocks and process starvations. From Filter Diagram we generate a timed automaton to check the respect of behavioral properties according to structural and arithmetic and/or logic operations. Model transformations used to generate formal artifacts from Structural and Filter diagrams generate a trace model for each transformation. The trace model is used later to trace back verification result in order to give a diagnosis support for the designer. Figure 4 shows an overview of the analysis process of our verification framework.

#### IV. APPLICATION: DETECTION OF AIMING DIRECTIONS IN A SHOOTING SIMULATOR

This example concerns the implementation of a tracking algorithm used in the development of an indoor small arms shooting simulator. This simulator implements multi-firing weapons. Each weapon has an infrared laser diode which diffuses an invisible beam materializing the line of sight of each shooter on the screen. An infrared camera delivers a video stream to which we apply a complex image processing algorithm to determine, with a sufficient precision and in real time, the aiming direction of each shooter.

##### A. Initial solution

The processing algorithm to be applied to the video stream is entirely deployed on a computer dedicated to managing the whole simulation process. This algorithm can be decomposed into two main phases. In the initialization phase we save a grayscale reference image of the scene displayed on the screen. During the second phase of processing each new image is converted to grayscale and then subtracted from the reference image before applying a threshold filter. The residual noise is reduced through a smoothing filter. This sequence of filters isolates highlight spots. At this stage, we proceed to the detection of blobs to determine their sizes and coordinates on the screen. All detected spots are injected to a tracking algorithm to assign each spot to its corresponding shooter.

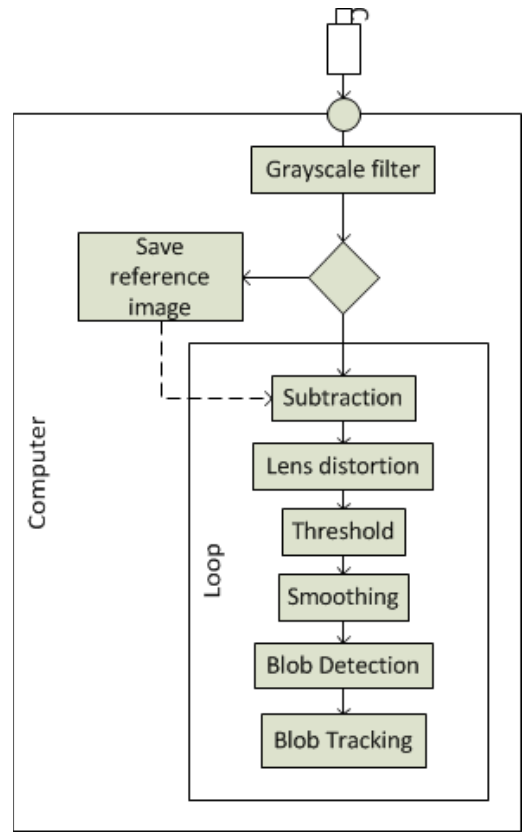

Figure 5. Description of the initial solution

The whole of this process was implemented on a computer using a conventional processor (intel Pentium IV, 2,4 GHz). Consequently, the system performances decrease significantly. indeed, we were forced to limit the video rate at 10 frames / second instead of a stream of 24 frames / second required for a proper analysis of the stability of the weapon before, during and after the shot as well as to reduce the image resolution from  $1028px \times 768px$  to  $600px \times 400px$ , which amplifies errors in calculating the coordinates of the points aimed at by shooters.

##### B. Adopted solution

To find a solution to the shortcomings of the original architecture described, we adopt a hardware implementation to parallelize some of the processing and comply with the time constraints required by this simulator. The figure below describes the new reached solution. We deploy a large part of the processing on a FPGA. After saving the reference image, each new image will be subject to a parallelized processing to extract a list of spots (blob List). Conversion operations to grayscale and subtraction have repetitive blocks which can be parallelized. The designed system will provide in output a list containing the coordinates and sizes of detected spots. This list will be injected into the tracking algorithm deployed on the computer dedicated to manage simulation.

Figure 8. result of image processing

### C. Hardware implementation

To implement the solution described above, we define a system (*SYSTEM*). This system has an input stream *Image* and a Boolean one called *first* injected into a conditional block to redirect to the initialization phase or to the processing one. The system provides a list of spots (Blobs list) in output. This processing will run while the video stream is available in input. We apply a succession of filters pipelined to perform a parallel processing to improve the execution time. The data stream split to five FIFO is injected into a pipelined processing with five filters. Each stage of processing can be parallelized internally while the computational tasks are independent. Diagrams are produced using a graphical tools created with *eclipse GMF* [11]. We use *ACCELEO* [12] to define transformation and generation rules to produce Handel-C code.

### D. Results

This hardware implementation allowed us to circumvent the limitations of a sequential implementation. We were able to meet the requirements of our simulator by improving the image stream at 23 images / second using a resolution of 1028px × 768px. Using *VIP DESIGN* allows us to minimize development effort and to reduce prototyping time. The following tables summarize the obtained results.

TABLE I. FPGA RESOURCE CONSUMPTIONS BY FILTERS

Filters	FPGA resource consumption	
	Configurable Logic Blocks (CLB)	Block RAM's
RGB2GRAY	454	1
LENSDISTORTION	1525	2
SUBTRACTION	326	1
THRESHOLD	294	1
SMOOTHING	652	2
BLOBDETECTION	1830	4

TABLE II. PERFORMANCE COMPARISON

Platforms	Performance				
	Frequency (Mhz)	Latency (ms)	Resolution (px×px)	Stream rate (image/sec)	Development effort
PC Intel P4, 2,4GHz	6,25	16	600×400	10	50h 3254 lines of code
FPGA, Cyclone II	16	4,34	1028×768	23	8h

Obtained results confirm the suitability of hardware implementation for image processing algorithms running under severe time constraints. Thus, we could significantly improve execution time to go from 16ms to 4,34ms. By using higher resolution and frame rate, we decreased errors when calculating shooter aiming directions. Being a visual tool, placing designer at a high level of abstraction and promoting the concept of reuse, VIP DESIGN reduces development time and improves the clarity of the solution. Handel-C code generated from the model created with VIP DESIGN is easy to understand by software developers because of its similarity with high level programming languages. However, the final solution implemented on FPGA doesn't reach a satisfactory level of optimization, as shown in table I, particularly in terms of occupation rate.

## V. CONCLUSION

Hardware implementation of image processing algorithms is an adequate solution to improve execution time and to optimize resource consumption. Several programming languages such as VHDL and Handel-C, are used to describe hardware systems. However, the increasing complexity and the need to reduce development time motivate the rise of graphical design tools to raise the abstraction level and overcome difficulties related to hardware concepts. We proposed VIP DESIGN, a new graphical language for embedded and real-time image and video processing systems design. The approach proposed by VIP DESIGN is based on the description of the system through the scheduling of several sequential or competitive filters communicating through channels and running at a speed set by the same or different clocks. This is possible by using two kinds of diagram that allow the designer to define the functional structure and the internal behavior of the system. The structural diagram describes the functional hierarchy of the system. Filter edition diagram is used to describe the internal behavior of each filter using an action language. Time constraints are expressed by integrating clauses adapted to real-time system design. For the verification of these constraints we integrated a formal verification framework that

generates formal models from our graphical diagrams. Generated code is putted in the input of the CADP-Toolbox for model checking behavioral and timed properties. We illustrate, through a real case of study, that the use of VIP DESIGN to design a real-time system allows a graphical representation to increase the visibility of the designed system and a rapid prototyping without hardware knowledge.

However, VIP DESIGN does not cover the entire design and development flow. To this end, the Handel-C code generated automatically from the produced model must be submitted to a verification and simulation process before its implementation. Actually, we use a tool provided by Celoxica [13] to simulate and compile generated code. Development of an owner simulator will be subject to future works.
